

Sparse Koopman Autoencoders for Multibasin Dynamical Systems

Induced latent sparsity makes the active support a label-free indicator of the relevant basin and local linear law.

01 • The Problem

Multibasin systems break a single global linearization

state space

Basin A

Basin B

Basin C

✗

A single global linear K cannot describe all basins simultaneously.

✓

Each basin admits a local linear description, but they are mutually incompatible.

02 • The Model

Sparse-coding Koopman autoencoder

x_t

Encoder E_θ (LISTA-style sparse code)

z_t

sparse latent code, active support $S(x_t)$

$\times K$

$\hat{z}_{t+1} = K z_t$

(linear advance within S)

Decoder D (linear)

$\hat{x}_{t+1}$

Periodic re-encoding.

Decode and re-encode every m steps so the support can change as the predicted state moves.

03 • The Key Idea

The active support tells us the basin and the local linear law

A

active support $S(x)$

$K|_{S_A}$

B

active support $S(x)$

$K|_{S_B}$

Different basin → different active support → different active columns of K → different effective local linear law.

Periodic re-encoding refreshes the support across regimes:

z_A

K^m

decode

encode

z_B

→ the support can switch when the trajectory crosses into another basin.

Core idea. Sparse latent code → active support agrees with basin → support routes prediction to a local linear law (no basin labels used during training).
